Abstract

To facilitate potential applications of water-in-supercritical CO₂ microemulsions (W/CO₂ μ Es) efficient and environmentally responsible surfactants are required with low levels fluorination. As well as being able to stabilize water-CO₂ interfaces, these surfactants must also be economical, prevent bio-accumulation and strong adhesion, deactivation of enzymes, and also be tolerant to high salt environments. Recently, an ion paired catanionic surfactant with environmentally-acceptable fluorinated C₆-tails was found to be very effective at stabilizing W/CO₂ μ Es with high water-to-surfactant molar ratios (W_0) up to ~50 (Sagisaka, M. et al. *Langmuir*, **2019**, 35, 3445–3454). As the cationic and anionic constituent surfactants alone did not stabilize W/CO₂ μ Es, this was the first demonstration of surfactant synergistic effects in W/CO₂ microemulsions. The aim of this new study is to understand the origin of these intriguing effects by detailed investigations of nanostructure in W/CO₂ microemulsions using high pressure small-angle neutron scattering (HP-SANS). These HP-SANS experiments have been used to determine the headgroup interfacial area and volume, aggregation number and **critical effective** packing parameter (**CPP EPP**). These SANS data suggest the effectiveness of this surfactant originates from increased **CPP EPP** and decreased hydrophilic/CO₂-philic balance, related to a reduced effective headgroup ionicity. This surfactant bears separate C₆F₁₃-tails and oppositely-charged headgroups, and was found to have a **CPP EPP** value similar to that of a double C₄F₉-tail anionic surfactant (4FG(EO)₂), which was previously reported to be one of most efficient stabilizers for W/CO₂ μ Es (maximum W_0 = 60-80). Catanionic surfactants based on this new design will **be** key for generating super-efficient W/CO₂ μ Es with high stability and water solubilization.

Keywords: Supercritical CO₂, Microemulsion, Catanionic Surfactant, Solubilizing Power, Small-Angle Neutron Scattering

Introduction

Supercritical CO₂ (scCO₂) is now widely used industrially as an alternative solvent to replace volatile organic compounds (VOCs) for organic synthesis, dry cleaning, polymerization, extraction, and nanomaterial processing amongst others¹. For these applications there are numerous advantages of scCO₂ such as low cost, non-toxicity, non-flammability, natural abundance, a solvent quality tunable by control over pressure and temperature, and elimination of energy-consuming solvent evaporation steps in separation processes¹. One of the drawbacks of pure scCO₂ for applications is the inherent low solubility of polar solutes: approaches to overcome this are required to help develop further industrial applications of scCO₂. An obvious way to enhance low solubility is through formation of water-in-scCO₂ (W/CO₂) dispersions, including microemulsions (μ Es) and macroemulsions (emulsions): numerous surfactants have been tested to accomplish this task²⁻¹³. However, conventional hydrocarbon (HC) surfactants typically used for analogous water-oil μ Es, including Aerosol-OT (sodium bis-(2-ethyl-1-hexyl) sulfosuccinate, AOT)¹⁴, are essentially incompatible with pure scCO₂³⁻⁷. On the other hand, some specialized tailor-made fluorocarbon (FC) surfactants have been found to display high affinity for scCO₂, and are able to stabilize W/CO₂ μ Es with modest water-to-surfactant molar ratios > 10 ($W_0 = [\text{water}]/[\text{surf}]$).⁷⁻¹³ These CO₂-philic FC surfactants may consist of either perfluoropolyether (PFPE)-tails, double FC-tail and FC-HC hybrid-tail structures.⁷⁻¹³ For example, a single PFPE-tail surfactant (PFPECOONH₄), a hybrid surfactant having perfluorohexyl and *n*-butyl tails (FC6-HC4), and double perfluorocarbon-tail surfactants (8FS(EO)₂, 8FG(EO)₂ and 4FG(EO)₂) (**Figure S1** for chemical structures) have been shown to stabilize W/CO₂ μ Es with maximum W_0 (W_0^{max}) values up to 20, 80 and 45-80, respectively.⁷⁻¹³ These surfactants mentioned are mainly anionic which presents problems for applications, including, difficulties of removing ionic surfactants from processes producing nanoparticles, deactivation with enzymatic reactions, surfactant-dye complexation in dyeing, and salting-out at high salinities typical in enhanced oil recovery (EOR)¹⁵⁻¹⁹. For industrial applications CO₂-philic surfactants should ideally be composed of (1) CO₂-philic tails with low fluorination for reducing cost and environmental impact, and (2) possess nonionic or weakly ionic headgroups to minimize salting out.

Earlier studies ^{20,21} investigated synergistic effects on interfacial properties of scCO₂-philic surfactants by mixing HC, FC and FC-HC surfactants (**Figure S1**). Mixing commercial nonionic HC surfactants (TMN-6 and L31, **Figure S1**) with fluorinated surfactants reduced the ~~mixed lower~~ critical microemulsion concentration (*c_{mc}*), **which is defined as the lowest surfactant concentration to yield a microemulsion**, compared to the individual surfactants, however, synergistic effects were not observed in terms of the water-solubilization W_0 ²⁰. On the other hand, mixing 8FS(EO)₂ and FC6-HC4 (**Figure S1**) increased W_0^{\max} by only 3 compared with the value for each surfactant at 75 °C and 400 bar, showing a very small synergistic effect ²¹.

In earlier studies of surfactant mixtures in conventional solvents, the combination of anionic and cationic surfactants was shown to result in strong synergism in terms of interfacial properties, stability of vesicles, reverse-type molecular assemblies and W/O dispersions ^{22,23}. In these cases, synergism is understood to originate from electrostatic interactions between oppositely charged headgroups. These cationic:anionic surfactant mixtures have been simplified further still, by synthesizing pure catanionic surfactants excluding the counterions.²⁴

A previous study reported synthesis of three pure catanionic surfactants ([C₆F₁₃mim][CF₃]₃S], [C₆F₁₃mim][C₆F₁₃S] and [C₅F₁₁mim][C₅F₁₁S], **Table S1 Figure 1**) bearing environmentally-acceptable short chain FC tails, and studied formation and properties of W/CO₂ μEs.²⁵ One of these surfactants, namely [C₆F₁₃mim][C₆F₁₃S], showed exceptional water-solubilizing power ($W_0^{\max} = \sim 50$), representing the first observation of surfactant synergism in W/CO₂ μEs. The catanionic surfactants were shown to display cloud point temperatures, rather than Kraft temperatures, suggesting the catanionic headgroup has some nonionic character²⁵.

To clarify the mechanism of synergism and ion pairing with these CO₂-active catanionic surfactants this study investigates phase behavior, solubilizing properties and self-assembly structure of W/CO₂ μEs at different pressures and W_0 values. Probe dye studies, using UV-vis absorption spectra with an ionic dye methyl orange was used to follow water uptake and high-pressure small-angle neutron scattering (HP-SANS) was used to determine microemulsion water droplet structures and sizes. The

SANS measurements have permitted an assessment of the **critical** effective packing parameter (**CPP** **EPP**, in other words, an intrinsic packing parameter relevant to an individual mixed system under certain experimental conditions)²⁶⁻²⁹ to **been** **be** made. The **CPP** **EPP** is a key index, indicating the preferred self-assembly structure, and is based on surfactant spatial packing, resulting from interactions with solvents (water and CO₂) and neighboring surfactant molecules. These results demonstrate that catanionic surfactants can offer new insight into the design criteria for inexpensive and environmental-friendly surfactants for W/CO₂ μ Es appropriate for industrial use.

Figure 1 Chemical structures of surfactant ions ($n = 5$ or 6).

Experimental Section

Materials

The catanionic surfactants $[\text{C}_6\text{F}_{13}\text{mim}][(\text{CF}_3)_3\text{S}]$, $[\text{C}_6\text{F}_{13}\text{mim}][\text{C}_6\text{F}_{13}\text{S}]$ and $[\text{C}_5\text{F}_{11}\text{mim}][\text{C}_5\text{F}_{11}\text{S}]$ (Table S1 supporting information Figure 1, purity > 95 %) used here were synthesized and purified as described in a previous study²⁵. Ultrapure water with a resistivity of 18.2 M Ω cm was obtained from a Millipore Milli-Q Plus system. CO₂ was of 99.99% purity (Ekika Carbon Dioxide Co., Ltd.)., and methyl orange was purchased from Acros organics and used without further purification.

Phase behavior observations and UV-visible absorption spectroscopy

A high-pressure (HP) cell with a metal-to-glass sealed glass window (KP-308-3, Nihon Klingage co., ltd) and a moveable piston inside the cell was employed to examine the phase behaviour of surfactant/water/scCO₂ mixtures by operating pressure and temperature. A detailed description of the experimental apparatus and procedures is given in earlier papers.^{12,13,25}

Uptake of water into W/CO₂ μEs was examined by UV-visible absorption spectroscopy measurements in a pressure cell (stainless steel SUS316: cell volume 1.5 cm³) with three quartz windows (thickness: 8 mm, inner diameter: 10 mm). The spectral measurements were performed with a double-beam spectrophotometer (Hitachi High-Technologies, Co., U-2810). Each window was positioned to provide a perpendicular 10-mm optical path. The windows were attached and fastened tightly to the stainless steel body of the cell with PTFE kel-F packing, thereby compressing the packing between the stainless steel parts and the windows, providing excellent sealing (tested up to 400 bar); temperature was controlled by circulating water thermostat bath.

The spectroscopic measurements of the water/surfactant/scCO₂ systems were performed at 350 bar and 45 or 75 °C. The densities of CO₂ were calculated using the Span-Wagner equation of state (EOS)^{26 30}. Pre-determined amounts of surfactant and CO₂, where the molar ratio of surfactant to CO₂ was fixed at 8×10^{-4} , were loaded into the optical cell. An aqueous solution containing methyl orange (MO)

as a trace marker dye (3 mM) was then added into the optical cell through a six-port valve until the clear single-phase Winsor-IV W/CO₂ μ E microemulsion converted into a turbid macroemulsion or hydrated surfactant was seen to precipitate. During spectroscopic measurements, the scCO₂ mixtures were stirred by a magnetic stirrer.

High-Pressure small-angle neutron scattering (SANS) measurements and data analyses

Due to the range of neutron wavelengths available, time-of-flight (T-O-F) SANS is suitable for studying the shapes and sizes of colloidal systems. High-pressure SANS (HP-SANS) is a particularly important technique for determining aggregated nanostructures in supercritical CO₂^{10,12,13,25}. The HP-SANS measurements were performed at 45 °C at various pressures using the SANS2D T-O-F instrument, at the Rutherford Appleton Laboratory at ISIS UK, in conjunction with a stirred, high-pressure cell (Thar). The cell path length and the incident neutron beam diameter were both 10 mm. The measurements gave absolute scattering cross sections $I(Q)$ (cm⁻¹) as a function of momentum transfer Q (Å⁻¹), which is defined as $Q = (4\pi/\lambda)\sin(\theta/2)$, where θ is the scattering angle. The accessible Q range was 0.002-1.0 Å⁻¹ on SANS2D arising from a white neutron beam with incident wavelengths, λ , of 2.2-10 Å. The data were normalized for transmission, empty cell, solvent background, and pressure induced changes in cell volume as before^{12,13,25}.

Pre-determined amounts of D₂O and surfactant, where the molar ratio of surfactant to CO₂ was fixed at 8.0×10^{-4} (= 16.7 mM at the appropriate experimental condition), were loaded into the Thar cell. Then CO₂ (11.3 g) was introduced into the cell by using a high-pressure pump, and the surfactant/D₂O/CO₂ mixture was pressurized to 120, 200 or 350 bar at 45 °C by decreasing the inner volume of the cell. Under vigorous stirring, visual observations were carried out to identify the mixture as being a transparent single-phase (W/CO₂ μ E) or a turbid phase. Finally, the HP-SANS experiments were performed for not only single-phase W/CO₂ μ Es, but also turbid phases formed below the cloud point phase transition pressure P_{trans} . Due to the systems being dilute dispersions (volume fractions typically \leq

0.012), the physical properties of the continuous phase of scCO₂ were assumed to be equivalent to those of pure CO₂. The scattering length density (SLD) of reversed micelle shells (ρ_{shell}) was calculated as $\rho_{\text{shell}} = 2.28 \times 10^{10} \text{ cm}^{-2}$. The SLDs of CO₂ (ρ_{CO_2}) and aqueous cores (ρ_{core}) containing the catanionic headgroup in the D₂O/CO₂ μE are variables of CO₂ density and W_0 , and are estimated as; $\rho_{\text{CO}_2} / (10^{10} \text{ cm}^{-2}) = 2.29$ at 350 bar, 2.03 at 200 bar, and 1.64 at 120 bar, and $\rho_{\text{core}} / (10^{10} \text{ cm}^{-2}) = 3.34$ at $W_0 = 5$, 4.15 at $W_0 = 10$, 4.62 at $W_0 = 15$, 4.92 at $W_0 = 20$, 5.13 at $W_0 = 25$, 5.28 at $W_0 = 30$ and 5.40 at $W_0 = 35$ as estimated in supporting information (see **S2**). As ρ_{shell} was close to ρ_{CO_2} and the shells are solvated with CO₂, neutron scattering from the shells was assumed to be negligible owing to the small contrast step. Therefore, SANS from the D₂O/CO₂ μE s was assumed to only be from the so-called aqueous core contrast. For model fitting data analysis, the W/CO₂ μE droplets were treated as ellipsoidal particles with a Schultz distribution in core radii^{27,31}. The polydispersities in ellipsoid radii were fixed at 0.3 as found in spherical D₂O/CO₂ μE s with the double FC-tail surfactants (polydispersity = 0.17-0.40)^{12,13,25}. Full accounts of the scattering laws are given elsewhere^{12,13,25,28,32}. Data have been fitted to the models described above using the SasView small-angle scattering analysis software package (<http://www.sasview.org/>)^{12,13,25,28,32}. The fitted parameters are the core radii perpendicular to the rotation axis ($R_{\text{f-ell,a}}$) and along the rotation axis ($R_{\text{f-ell,b}}$) for ellipsoidal particles; prior to full model fitting micellar dimensions were initially estimated by Guinier analysis ($R_{\text{g-sph}}$)^{29,33}. The catanionic reverse micelles have C₆-perfluorocarbon tails shells, which weakly interact with other²⁵. The hard sphere model was employed as an effective $S(Q)$ for all W_0 values.

Results and Discussion

Aggregation behavior of catanionic surfactant reverse micelles in water/supercritical CO₂ mixtures

In a previous study, visual observation and FT-IR spectra measurements for 16.7 mM [C₆F₁₃mim][C₆F₁₃S]/W/CO₂ μ Es were conducted.²⁵ Those results showed formation of transparent single-phases W/CO₂ μ E ~~as shown~~ at pressures above P_{trans} in **Fig. S2**, and absorbance characteristic of hydrogen bonded water increased with loading water over the W_0 range from 0 to 50 at 45 °C and 350 bar, ~~consistent with~~ suggesting a high water-solubilizing power of $W_0^{max} = 50$.²⁵ Here, to confirm this observation, solubilization of water and the tracer ionic dye (aqueous methyl orange MO 3 mM) by [C₆F₁₃mim][C₆F₁₃S] reverse micelles was examined. The dye solution was loaded into 16.7 mM catanionic surfactant/CO₂ mixtures, and the UV-vis adsorption spectra were measured at different W_0 values. Alone, MO does not dissolve in pure CO₂ but it does dissolve in water, and is generally incorporated within the water-rich pockets of single-phase W/CO₂ μ Es, dyeing the systems red.^{12,13} The surfactant [C₆F₁₃mim][C₆F₁₃S] formed transparent and reddish single-phase CO₂ systems with the MO solution, however, the other catanionic surfactants always remained as precipitates, yielding undyed CO₂ phases.

The UV-vis spectra of MO for [C₆F₁₃mim][C₆F₁₃S] and the other catanionic surfactants are displayed in **Figures 12** and **S3** (supporting information), respectively. At 45 °C the spectra showed large and broad absorption peaks of MO, and an absorbance maximum (λ_{max}) at ~418 nm independent of W_0 . As λ_{max} is known to shift to longer wavelengths^{12,13} when MO molecules are solubilized in more polar environments, hence λ_{max} can be employed to gauge microenvironment polarity. Previous experiments with W/CO₂ μ Es with anionic hybrid surfactants FC6-HC n and double FC-tail surfactants n FG(EO)₂ and n FS(EO)₂ displayed λ_{max} values at ~420 nm even at different W_0 values and temperatures of 45 and 75 °C,^{12,13} consistent with free MO molecules solubilized in the aqueous cores. The similar λ_{max} values for anionic and catanionic surfactants imply that the microenvironmental polarity surrounding MO molecules was essentially unaffected by the different kinds of headgroups, most likely as a result of weak interactions between headgroups and MO molecules.

Figure 12 UV-vis spectra of 16.7mM [C₆F₁₃mim][C₆F₁₃S]/water/CO₂ mixtures with different W_0 values at 350 bar and 45 °C (Top) or 75 °C (bottom). 3 mM methyl orange aqueous solution was loaded as a dispersed aqueous phase.

Interestingly, the λ_{\max} values blue-shifted to ~314 nm elevating temperature from 45 °C to 75 °C, suggesting a notable change in microenvironment. Such blue shifts with MO have been reported in studies in MO/catanionic surfactant/water mixtures, explained by generation of ion pair complexes of MO and cationic surfactants.^{30 34} This suggests that at the high temperature cation-anion dissociation of the catanionic surfactant promoted and then formed anionic MO-cationic [C₆F₁₃mim] ion pair complexes.

As shown in **Figure 12**, the adsorption peaks grew on increasing the dosing of MO solution and the systems remained transparent. To determine the maximum water solubilization (W_0^{\max}) of the surfactant at each temperature, the maximum absorbance was plotted as a function of W_0 as shown in

Figure S4. The linear behavior seen over the W_0 ranges of 0-61.2 at 45 °C and of 0-102 at 75 °C is consistent with W_0^{\max} values to be ~60 and ~100, respectively. The W_0^{\max} value at 45 °C was in line with results from FT-IR spectroscopy in a previous study ($W_0^{\max} = \sim 50$)²⁵. Such a high value for W_0^{\max} over 50 is quite rare and can be identified with a highly efficient surfactant for stabilizing W/CO₂ microemulsions. On the other hand, no MO absorption was observed for the catanionic surfactants [C₆F₁₃mim][(CF₃)₃S] and [C₅F₁₁mim][C₅F₁₁S] (**Figure S3**), suggesting that droplet W/CO₂ μ Es, do not form. Since the constituent surfactants of these catanionic surfactants are insoluble and unable to stabilize W/CO₂ μ Es,²⁵ the synergistic effect of pairing of surfactant anions and cations has been clearly demonstrated by the formation of [C₆F₁₃mim][C₆F₁₃S]/W/CO₂ microemulsions, which have notably enhanced stability at 75 °C.

An important question remaining from the previous study²⁵ is “why does only [C₆F₁₃mim][C₆F₁₃S] stabilize W/CO₂ μ Es, whereas the other surfactants do not?”. The structural differences between [C₆F₁₃mim][(CF₃)₃S], [C₆F₁₃mim][C₆F₁₃S] and [C₅F₁₁mim][C₅F₁₁S] are small, with just two more CF₂ units for [C₆F₁₃mim][C₆F₁₃S] than the others. Based on previous studies^{7,12,13,28,32} the longer double FC-tails in [C₆F₁₃mim][C₆F₁₃S] would be expected to lead to higher CO₂-philicity and a greater solubility in scCO₂. It seems that the total fluorination is important, and for this class of surfactants there is a critical number of 12 fluorinated carbons needed for stabilization of microemulsions. In other words, surfactants must (1) be sufficiently compatible (soluble) in scCO₂ to adsorb strongly at the water-CO₂ interface and (2) have sufficiently thick FC-shells to maintain droplet stability. These phase behavior studies indicate that [C₆F₁₃mim][C₆F₁₃S] is an optimized surfactant for stabilizing W/CO₂ μ Es with high water loadings over $W_0^{\max} > 50$. Furthermore, despite the different catanionic structure, this twin-tailed surfactant is comparable to other super-efficient CO₂-philic surfactants 8FG(EO)₂ and FC6-HC4 which instead bear two tails covalently bound to the anionic headgroup^{7,12,13,28,32}.

Nano-structure of the catanionic surfactant/W/CO₂ microemulsions

A previous study of [C₆F₁₃mim][C₆F₁₃S]/W/CO₂ μ Es with $W_0 = 10$ at 350 bar and 45 °C²⁵, the SANS profiles were showed the HP-SANS profiles to be consistent with an ellipsoidal form factor model. To clarify changes in the core nanostructure with W_0 and pressure, SANS $I(Q)$ profiles were measured at 45 °C, $W_0 = 5$ -35 and $P = 120$ -350 bar. SANS data along with the fitted $I(Q)$ functions are shown in **Figure 2 3** (or **Figure S5**). The SANS profiles of [C₆F₁₃mim][C₆F₁₃S]/D₂O/CO₂ mixtures with $W_0 \leq 20$ -25 at 200-350 bar and ≤ 10 at 120 bar show a gradient of ~ 0 for the $\log [I(Q)] - \log Q$ plot at $Q < 0.03 \text{ \AA}^{-1}$, suggesting formation of globular nanosized D₂O cores. All SANS data were always measured under stirring. On the other hand, when W_0 was ≥ 25 at 200-350 bar the scattering intensity increased with decreasing Q at $Q < 0.02 \text{ \AA}^{-1}$ displaying gradients of $\sim Q^{-4}$. At high W_0 values ≥ 25 separated water probably remained in the systems, and was dispersed as equilibrium W/CO₂ emulsion droplets owing to the stirring W/CO₂ μ Es. The SANS also showed gradients of $\sim Q^{-4}$ at $Q < 0.02 \text{ \AA}^{-1}$.

As a first step in SANS data analysis, Guinier^{29 33} and Porod^{34 35} plots were used to estimate the D₂O core radii (**Figures S6 and S7**), and the results are listed in **Table S2 S1**. The Porod plot asymptote at high Q can be used to analyze interfacial area per surfactant molecule^{34 35}. Unfortunately, reliable asymptotic $\{I(Q) Q^4\}_{Q \rightarrow \infty}$ values could not be obtained due to a combination of weak scattering and background noise as shown in **Figure S7**. SANS data were also analyzed with Ornstein-Zernicke formalism to investigate density fluctuations in a system approaching critical demixing or phase separation.³⁶⁻³⁸ The correlation lengths ξ , showing sizes characteristic of such structural domains are plotted as a function of W_0 in **Figure S8 S9**. The ξ values were found to increase from $\sim 12 \text{ \AA}$ to $\sim 30 \text{ \AA}$ with increasing W_0 from 10 to 35 and the increasing trends of ξ were similar to those radii obtained from Porod (R_{p-sph}) and form fitting analysis (**Figure 4**). The R_{g-sph} values from Guinier analysis were employed as initial radii in the subsequent fitting using models for polydisperse Schultz spherical or ellipsoidal particles, as appropriate for giving the best fits. In the case of ellipsoids, both oblate and prolate aspect ratios were compared (**Figure S5**), and the prolate model gave better fits.

Figure 2 3. SANS profiles of D₂O/CO₂ μE with 16.7 mM [C₆F₁₃mim][C₆F₁₃S] with different W_0 values at 45 °C and 120-350 bar. Solid lines are theoretical curves of prolate ellipsoid particle model fitted to the experimental data.

The model fit parameters for the prolate D₂O core μ E droplets ($R_{f-ell,a}$ and $R_{f-ell,b}$) are listed in **Table S3**. To demonstrate droplet growth with increased loading water, equatorial (R_{ell-a}) and polar (R_{ell-b}) radii of prolate D₂O cores are plotted in **Figure 3 4** as a function of W_0 at pressures ≥ 200 bar.

Figure 3 4. Change in prolate ellipsoid radii (R_{ell-a} and R_{ell-b}) for 16.7 mM [C₆F₁₃mim][C₆F₁₃S]/D₂O/CO₂ μ E cores as a function of W_0 at 45 °C and 200 bar or 350 bar.

As seen in **Table S3** at 120 bar the radii reduced with increasing W_0 from 5 to 10, which was accompanied by a phase transition from transparent μ Es to turbid phases (i.e. Winsor IV \rightarrow stirred Winsor II W/CO₂ microemulsions). On the other hand, at pressures ≥ 200 bar, the oblate radii increased linearly with W_0 as up to $W_0 = 25$, being described by $(R_{ell-a} / \text{\AA}) = a_{ell-a} + b_{ell-a} W_0$ and $(R_{ell-b} / \text{\AA}) = a_{ell-b} + b_{ell-b} W_0$ (where a_{ell-a} , b_{ell-a} , a_{ell-b} , $b_{ell-b} = 10.0, 0.58, 13.0, 1.84$ at 200 bar, and $5.79, 0.65, 14.7, 1.47$ at 350 bar. Eventually, the radii reached $R_{ell-a} = \sim 26 \text{ \AA}$ and $R_{ell-b} = \sim 63 \text{ \AA}$ at 200 bar, and $R_{ell-a} = \sim 22 \text{ \AA}$ and $R_{ell-b} = \sim 61 \text{ \AA}$ at 350 bar. This is consistent with swelling behavior with loading water as commonly reported in W/O and W/CO₂ reverse microemulsions^{13,28,32,39}. The radii values seemed to plateau for $W_0 > 30$ and visually these systems were turbid, consistent with stirred separating Winsor II phases. The slight discrepancies with W_0^{\max} obtained by spectroscopically may be due to weak stirring power in the pressure

cell and/or use of D₂O instead of H₂O needed for the HP-SANS experiments. In contrast with the increasing trend of radii with W_0 , the aspect ratios ($R_{\text{ell-b}} / R_{\text{ell-a}}$) were very similar (1.8-2.9) and seemed to be independent of pressure and W_0 as shown in **Figure S8 S9 S10**. The formation of elongated reverse micelles is an interesting observation, and is expected to increase CO₂ viscosity, which may find applications in CO₂-EOR efficiency ^{13,33,34 40,41}. Using equations (**S3 S4**) and (**S4 S5**) in supporting information (Sec **S7 S9**), apparent intrinsic and specific viscosities, $[\eta]$ and η_{sp} , were estimated (**Table S3**). The viscosity enhancements predicted this way would only be modest, ~13 % or less compared with that of pure CO₂. Hence, higher surfactant concentration could be needed to promote higher CO₂ thickening.

Previous SANS studies of double FC-tail surfactants $n\text{FG}(\text{EO})_2$ with different FC lengths ($n = 4-8$) also found a linear relationship between spherical D₂O core radius, R_c , and W_0 where $R_c = a + b W_0$, and the constants $a = 5.0-5.4$ and $b = 0.60-0.64$ ^{28 32}. The average values a and b of prolate core radii for [C₆F₁₃mim][C₆F₁₃S]/D₂O/CO₂ microemulsions, namely $a = (2a_{\text{ell-a}} + a_{\text{ell-b}})/3$ and $b = (2b_{\text{ell-a}} + b_{\text{ell-b}})/3$, were 11.0 and 1.00 at 200 bar and 8.8 and 0.92 at 350 bar, and these are 1.7-2.1 and 1.5-1.6 times larger than those for $n\text{FG}(\text{EO})_2$, respectively. For spherical geometry the volume of surfactant headgroup (v_{head}) and area per surfactant molecule (A), respectively are related by equation (1)

$$\alpha(p) R_c = (3v_{\text{head}}/A) + (3v_w/A) W_0 \quad (1)$$

where $\alpha(p) = 1 + 2p^2$, p is polydispersity index (σ/R_c), R_c is the core radius, and v_w is volume of a water molecule ^{13,28 32}. It follows that the larger a and b values suggests [C₆F₁₃mim][C₆F₁₃S] to have a larger v_{head} and a smaller A than for the $n\text{FG}(\text{EO})_2$ series. Based on Equation (1), a volume-to-surface area ratio per aqueous core in reverse μE ($v_{\text{core}}/s_{\text{core}}$) can be expressed as,

$$\alpha(p) (v_{\text{core}}/s_{\text{core}}) = (v_{\text{head}} N_{\text{agg}} + v_w W_0 N_{\text{agg}}) / (A N_{\text{agg}}) = (v_{\text{head}}/A) + (v_w/A) W_0 \quad (2)$$

where N_{agg} is aggregation number. ^{13,28 32} An advantage of using Equation (2) is that it can be applied to a wide range of morphologies (spheres, ellipsoids, rods etc), whereas Equation (1) relates only to spherical morphology. Using equation 2 and assuming constant v_{head} and A for [C₆F₁₃mim][C₆F₁₃S], ($v_{\text{core}}/s_{\text{core}}$) values calculated from $R_{\text{ell-a}}$ and $R_{\text{ell-b}}$ were plotted as a function of W_0 , as displayed in **Figure 4 5**.

Figure 4-5. Change in $(v_{\text{core}}/s_{\text{core}})$ of prolate cores in 16.7mM $[\text{C}_6\text{F}_{13}\text{mim}][\text{C}_6\text{F}_{13}\text{S}]/\text{D}_2\text{O}/\text{CO}_2$ μEs as a function of W_0 at 45 °C and 200 bar or 350 bar.

The $(v_{\text{core}}/s_{\text{core}})$ data at $W_0 \leq 25$ were expressed as linear functions, suggesting v_{head} and A can be calculated using Equation (2). The values of A , v_{head} , and radius of headgroup ($R_{\text{head}} = (3v_{\text{head}} / 4\pi)^{1/3}$) obtained from the slopes and the intercepts were $(A, v_{\text{head}}, R_{\text{head}}) = (105 \text{ \AA}^2, 459 \text{ \AA}^3, 4.8 \text{ \AA})$ at 200 bar and $(101 \text{ \AA}^2, 284 \text{ \AA}^3, 4.1 \text{ \AA})$ at 350 bar. At the higher pressures, the headgroup area and volume became smaller, implying a decrease in surfactant cation-anion pair dissociation and/or a decrease in the portion of the head groups immersed in the aqueous cores owing to increased solvation of surfactant tails by CO_2 at the higher pressure (density). Therefore, the increased CO_2 pressure (or density) affects not only tail- CO_2 solvation but also interactions between anionic and cationic headgroups. This could lead to a larger **CPP** **EPP** and a lower HCB resulting to the smaller $R_{\text{ell-a}}$ and $R_{\text{ell-b}}$ (i.e. a larger curvature for smaller droplets) at the higher pressures. As compared with anionic double FC-tail surfactants having a sulfonate group, the A and v_{head} values of $[\text{C}_6\text{F}_{13}\text{mim}][\text{C}_6\text{F}_{13}\text{S}]$ at 350 bar are similar to the $n\text{FG}(\text{EO})_2$ and $n\text{FS}(\text{EO})_2$ (e.g. A and v_{head} were 117-129 \AA^2 and 199-231 \AA^3 for the fluorinated surfactants in W/CO_2 μEs at 45 °C and 350 bar, respectively). This is interesting, because of the very different head group structures

comparing these two classes of surfactants. The implication is that the high water solubilization capacities of [C₆F₁₃mim][C₆F₁₃S] in W/CO₂ μ Es are linked to the electrostatic ion-pairing, promoting larger CPP EPP and lower HCB values comparable to those of the super-efficient double FC-tail surfactants^{7,12,28 32}.

For these [C₆F₁₃mim][C₆F₁₃S] surfactants in scCO₂, the reverse micelle aggregation number (N_{agg}) and occupied area per surfactant molecule at the W/CO₂ microemulsion interface ($A_{C/W}$) were calculated using the following equations.

$$N_{agg} = C_{surf}/C_{micelle} \quad (3)$$

$$C_{micelle} = (V_{D2O} C_{D2O} + V_{head} C_{surf})/(V_{core}) = C_{surf} (V_{D2O} W_0 + v_{head} N_A)/(v_{core} N_A) \quad (4)$$

$$A_{C/W} = s_{core}/N_{agg} \quad (5)$$

where N_A is Avogadro's number, C_{surf} and C_{D2O} , $C_{micelle}$ are molar concentrations of surfactant, D₂O and reverse micelle, v_{core} is volume per D₂O core, V_{D2O} , V_{head} , and V_{core} are molar volumes of D₂O, surfactant headgroups and D₂O cores plus headgroups ($V_{head} = v_{head} N_A$, $V_{core} = v_{core} N_A$), respectively. For the calculation of $A_{C/W}$ calculation, s_{core} is surface area per D₂O core, being calculated using the ellipsoid radii ($R_{f-ell,a}$ and $R_{f-ell,b}$) as well as the calculation of v_{core} for $C_{micelle}$.

According to theory^{35,36 26-29} the CPP EPP spontaneous packing parameter (SPP) can be also obtained by

$$CPP EPP SPP = v_{tail}/(A_{C/W} A_0 l_{tail}) \quad (6)$$

where v_{tail} and l_{tail} are hydrophobic tail volume and length, respectively. These symbols have the same meanings as in the expression of the EPP.²⁹ Entropy is taken into account by the fact that the area per molecule minimizes the free energy of the surfactant film (A_0 is the area that minimizes the free energy). According to this approach reverse micelles would be obtained with CPP EPP SPP > 1 (reversed cores form if the surfactant tails orient upward) to ~1 (cylindrical). In the case of W/CO₂ μ Es, EPP values should be calculated by taking account of solvation of the head and tail groups with water and CO₂ into the A_0 and v_{tail} values. If the hydrophobic part is assumed to be a truncated cone, the volume should be^{13,28 32}

$$v_{tail} = l_{tail} \{A_{C/W} + A_{tail} + (A_{C/W} A_{tail})^{0.5}\}/3 \quad (7)$$

where A_{tail} is area per hydrophobic tail terminus, respectively. When A_0 is replaced by $A_{C/W}$ for the calculation of EPP in W/CO₂ μ Es, Then Eq. (6) can be simply expressed as

$$\text{CPP EPP} = \{s_{\text{micelle}} + s_{\text{core}} + (s_{\text{micelle}} s_{\text{core}})^{0.5}\} / (3s_{\text{core}}) \quad (8)$$

where s_{micelle} is surface area per reverse micelle. In this study, the values of s_{micelle} were calculated from the ellipsoid core radii ($R_{\text{f-ell,a}}$ and $R_{\text{f-ell,b}}$), with surfactant tail length l_{tail} assumed to be 13.6 Å (between the terminal F-atom and the C-atom bearing the sulfonate group). All the values of $A_{\text{C/W}}$, N_{agg} and EPP obtained by Eqs. (3)-(8) are based on the assumption that all surfactant molecules are adsorbed at the W/CO₂ interface. In actual W/CO₂ μEs, it is likely that some surfactant molecules will partition away from the interface. However, this is estimated to be negligible compared with total number of associated surfactant molecules (8.0×10^{-2} mol%), taking into account very low critical microemulsion concentrations in scCO₂ for fluorinated ionic surfactants, which is typically $< 10^{-4}$ mol %.⁴² The calculated aggregation properties N_{agg} , $A_{\text{C/W}}$, and CPP EPP for the prolate droplets are listed in **Table S4**. The $A_{\text{C/W}}$ values were 118-134 Å² at W_0 values of 10-30 and are very close to those of $n\text{FG}(\text{EO})_2$ and $n\text{FS}(\text{EO})_2$ as mentioned above.^{28 32}

Figure 5 6 shows changes in N_{agg} and CPP EPP as a function of W_0 for [C₆F₁₃mim][C₆F₁₃S]/D₂O/CO₂ microemulsions at 45 °C and 200 and 350 bar, using data from **Table S4**. For comparison purposes, the figures also include literature data for double-tail surfactants $n\text{FG}(\text{EO})_2$ ($n = 4$ and 8) in W/CO₂ μEs^{28 32} and the common hydrocarbon surfactant AOT but in W/*n*-heptane μEs^{37 43}.

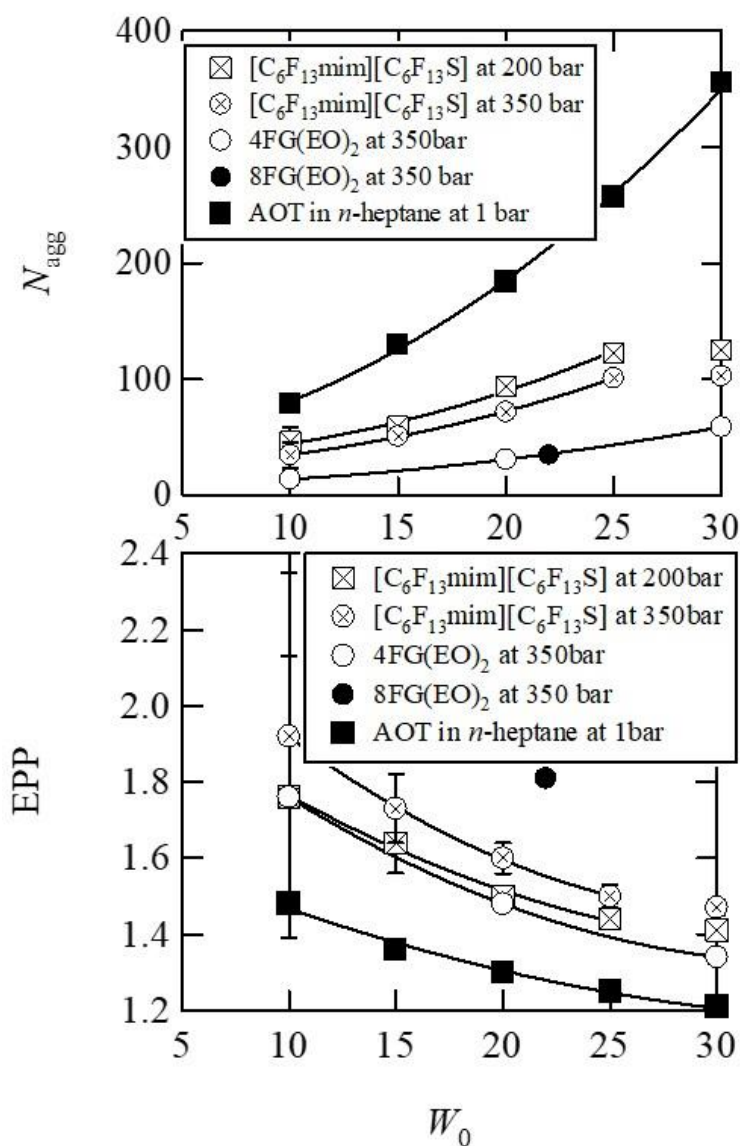

Figure 5 6. Changes in aggregation number (N_{agg}) and critical effective packing parameter (EPP) of surfactants as a function of W_0 . The data were for D₂O/CO₂ μ Es containing 16.7 mM [C₆F₁₃mim][C₆F₁₃S] and 50 mM double FC-tail surfactants (4FG(EO)₂ and 8FG(EO)₂) at 45 °C and W/*n*-heptane μ Es containing 50 mM AOT at 25 °C.

As reported for other reverse micellar systems with AOT^{37 43} and the double FC-tail surfactants²⁸³², N_{agg} and $\frac{CPP}{EPP}$ for $[C_6F_{13}mim][C_6F_{13}S]$, respectively, increased and decreased with W_0 , until the single phase μEs became unstable and turbid phases appeared. This is consistent with an increase in aggregation number for both surfactant and water, as well as a change in surfactant molecular morphology from a reversed truncated cone to a cylindrical shape. These changes are linked to growth of reverse micelles and a decrease in negative curvature of the W/CO_2 interface with increasing water loading. As compared to the double FC-tail anionic 8FG(EO)₂ and 4FG(EO)₂ surfactants, the catanionic $[C_6F_{13}mim][C_6F_{13}S]$ generates reverse micelles with larger N_{agg} values than those anionics. This implies that headgroup ion-pairing promotes dense packing of $[C_6F_{13}mim][C_6F_{13}S]$ molecules to favor reverse micelles owing to reduced electrostatic repulsion between headgroups. On the other hand, lowering the pressure from 350 to 200 bar increased N_{agg} and decreased $\frac{CPP}{EPP}$ for $[C_6F_{13}mim][C_6F_{13}S]$, presumably due to a promotion of molecular aggregation owing to a reduction in CO_2 solvation of the fluorinated tails at the lower CO_2 density. Comparing the $A_{C/W}$ and v_{head} values for $[C_6F_{13}mim][C_6F_{13}S]$ and the fluorinated double-tail 8FG(EO)₂ and 4FG(EO)₂, shows $\frac{CPP}{EPP}$ was relatively close to that of 4FG(EO)₂ but far from the value for 8FG(EO)₂. Since these two surfactant classes have similar $A_{C/W}$ values, the difference in $\frac{CPP}{EPP}$ between them is likely due to the fluorination level of the tails, namely longer FC-tails have the capacity to solvate more CO_2 molecules, giving rise to greater effective tail volumes. As compared with AOT/ W/n -heptane μEs ^{37 43}, the W/CO_2 μEs had smaller N_{agg} and larger $\frac{CPP}{EPP}$ values. This may be linked to differences in surfactant tail-solvent interactions, in other words, better solvation for the FC-tails with CO_2 , as compared to for the AOT-tails with n -heptane.

This study demonstrated that the $\frac{CPP}{EPP}$ of this catanionic surfactant, comparable to that of anionic double FC-tail surfactants, enables stabilization of W/CO_2 microemulsions with high W_0 values. This is very interesting as ionic headgroups themselves are known to be insoluble in supercritical CO_2 and surfactants having ionic head groups usually require long and/or multiple CO_2 -philic tails to stabilize W/CO_2 microemulsions. However, it is now apparent that mixing single CO_2 -philic tail anions and cations,

which are alone mostly insoluble and incompatible with CO₂, is a useful approach to design CO₂-philic surfactants.

Conclusions

Technologies based on supercritical CO₂ are applied in different industrial processes such as extraction¹⁸, dyeing³⁸, metal plating³⁹, organic synthesis¹⁶, polymerization⁴⁰, nanomaterial processing⁴¹ and dry cleaning.¹⁷ Formation of stable water/CO₂ dispersions will lead to improved efficiency and effectiveness, as well as to new applications, using otherwise CO₂ insoluble polar materials. A range of W/CO₂ μ Es are now available, but fluorinated surfactants are still required, and this limits potential commercial, industrial and environmental applications. The most important issues to address are lowering both the cost and fluorination of CO₂-philic surfactants, and to reduce their ionic character to minimize strong adhesion to surfaces deactivation of enzymes¹⁹, and loss of surface activity in high ionic strength media (such as sea water).

In order to meet these requirements for potential use of W/CO₂ μ Es in industrial processes¹⁶⁻¹⁸, W/CO₂ μ Es have been studied here, stabilized by ion-pairs of low F-content surfactant anions and cations, which themselves are individually insoluble and surface-inactive in scCO₂. Because the ions are strongly associated, they cannot be easily dissociated under ambient conditions, as such, catanionic surfactants are not classified as normal ionic surfactants^{25,42,43 44,45}.

This study was conceived to answer the question “why are ion-paired catanionic surfactants so effective at stabilizing high water content W/CO₂ μ Es”? The three new significant findings are:-

- (1) The W/CO₂ μ Es with [C₆F₁₃mim][C₆F₁₃S] solubilized an ionic dye which acts as a microenvironmental polarity probe, showing behavior similarity to other fluorinated anionic surfactants.^{9,12}. On the other hand, the other catanionic surfactants with lower F-content did not solubilize the dye in scCO₂, which is consistent with a lack of W/CO₂ μ E stabilization.
- (2) Aggregation numbers of reverse micelles were about two times larger for [C₆F₁₃mim][C₆F₁₃S] compared with fluorinated double-tail anionic surfactants^{28 32} implying that electrostatic interactions between cationic and anionic headgroups promote close packing of surfactants to stabilize reverse micelles.

(3) ~~Critical~~ Effective packing parameter (~~CPP~~ EPP) values of the catanionic surfactant in W/CO₂ μ Es were relatively close to those found previously for the double perfluorooctyl-tail anionic surfactant 4FG(EO)₂^{28 32}. This indicates the electrostatic interactions resulted in a small interfacial areas and volumes for the catanionic headgroups, which is required for reversed curvature self-assembly, as found for the sulfonate headgroup of 4FG(EO)₂^{28 32}.

From these findings and previous studies²⁵, the efficiency of [C₆F₁₃mim][C₆F₁₃S] is likely related to ~~CPP~~ EPP and HCB values which are comparable to those of double FC-tail anionic surfactants^{28 32}. Such a large EPP and a low HCB would be consistent with the small area and low ionicity of the catanionic headgroup, as compared to the related single-tail and single ionic headgroup anionic and cationic surfactants (Na[C₆F₁₃S] and [C₆F₁₃mim][CH₃SO₃]). Hence, the concept of surfactant anion-cation pairing represents a new platform for developing CO₂-philic surfactants and water-in-CO₂ microemulsions for practical applications. This surfactant may be thought of as “the goose (cheap, simple-structure, and CO₂-inactive surfactants) that lays the golden egg (super-efficient CO₂-philic solubilizer)”. Using this platform but with highly-methylated alkyl tails, it should be possible to generate cheap and simple hydrocarbon surfactants as a super-efficient CO₂-philic solubilizers, which is a long-cherished dream in supercritical CO₂ science and technology.
